(57) **ABSTRACT**

In one embodiment, an elevator controlling method includes calculating the positional value of an elevator driving motor the every first cycle; generating a control signal every third cycle to control the motor based on the calculated positional value and the rotational speed of the motor calculated every second cycle; and controlling the driving power source of the motor based on the generated control signal.

METHOD OF CONTROLLING ELEVATOR MOTOR ACCORDING TO POSITIONAL VALUE AND ROTATIONAL SPEED

CROSS-REFERENCE TO RELATED APPLICATIONS

Pursuant to 35 U.S.C. §119(a), this application claims the benefit of earlier filing date and right of priority to Korean Patent Application No. 10-2011-0123880, filed on Nov. 24, 2011, the contents of which are hereby incorporated by reference herein in its entirety.

BACKGROUND

The embodiment relates to an elevator controlling method and device, and an elevator using the same. More particularly, the embodiment relates to an elevator controlling method and device, and an elevator using the same that may enhance control performance.

In general, an elevator is used to make people get in and move them up and down in a high-rise building or is used to load and transport cargo. The elevator goes up and down by the driving of a hoist, a kind of a driving device, in an elevator shaft installed in the high-rise building. In addition, an elevator car that has a given space where people may get in or cargo may be loaded is connected and installed to the hoist.

In addition, a 3-phase industrial inverter that generally replaces a DC motor and is used for an elevator driving motor may torque-control an AC motor through vector control.

The brake of an elevator may be controlled by the control of an inverter. When the brake of such an elevator opens, a car shakes, which is called rollback. A load-cell that is a sensor device for measuring the weight is generally used to decrease rollback, and the rollback of an elevator car may decrease using the weight sensing of such a load-cell.

However, a method is being recently developed, which may decrease rollback without load-cell by loading a control algorithm in an inverter itself used for the speed control of an elevator, to increase the reliability matter and the efficiency in speed control of a load-cell sensor.

To decrease rollback, it is important to quickly follow a torque corresponding to the size of a load, which is called load compensation.

FIG. 1 is a diagram for describing an example of a speed controlling device according to the related art to decrease such load compensation.

Referring to FIG. 1, an elevator controlling device, such as P-PI mechanics according to the related art may include a position controlling unit 10, a speed controller 11, a motor speed measuring unit 12, and an inverter 14.

The position controlling unit 10 acquires a position-controlled value θ for controlling a position and an actual positional value θ^* , finds the difference between them, multiplies the difference value by a proportional gain value KPP, and outputs a speed-controlled value.

In addition, the speed controller 11 applies proportional gain KP and integral gain KI to the difference between the speed-controlled value and the speed value received from the motor speed measuring unit 12, adds the value, and outputs it as a torque-controlled value T*.

The inverter 14 receives the torque-controlled value a load T1 applied to a motor due to the weight of a car, a rope, passengers, etc. at the elevator, and controls the speed of an elevator. In addition, if an actual speed ω and an actual position θ are measured from the motor controlled by the inverter

2

14, they may be feedback as the input of the position controlling unit 10 and the speed controller 11.

The inverter 14 makes an actual torque through vector control according to a torque-controlled value and controls speed. The vector control may be performed on current that has been divided into magnetic flux controlling components and torque controlling components. J means an inertia value, S means a Laplace operator, and 1/S means integral.

The transfer function of the elevator controlling device according to the related art is represented by the following Equation 1.

$$\theta = \frac{s}{Js^3 + Kps^2 + (K_I + K_{PP}K_P)s + K_{PP}K_I} T_i \quad \langle \text{Equation 1} \rangle$$

If designing a pole in case of the elevator controlling device according to the related art, there is a problem that it is difficult to freely arrange the pole. The coefficients of a transfer function are not independent from one another and include the product and sum of gains. Thus, if a gain changes, then two or more coefficients change. As a result, it is not possible to freely design a pole.

In addition, in case of triple root, there is a problem that it is not possible to arrange a pole itself. The reason is that if a discriminant is applied under the assumption of triple root, there is no root value that makes both the discriminant of the cubic equation and the discriminant of the quadratic equation resulting from differentiation of this on the right term in Equation 1 zeros.

SUMMARY

An embodiment provides an elevator controlling method that may enhance control efficiency.

Embodiments also provide a control device and a control method that may decrease a rollback phenomenon at an elevator without a load-cell.

Embodiments also provide an elevator controlling device and method, and an elevator including the same that may effectively decrease a rollback phenomenon through a state estimating unit.

In one embodiment, an elevator controlling method includes calculating the positional value of an elevator driving motor the every first cycle; generating a control signal every third cycle to control the motor based on the calculated positional value and the rotational speed of the motor calculated every second cycle; and controlling the driving power source of the motor based on the generated control signal.

In addition, the generating of the control signal may further include estimating the rotational speed of the motor by the control signal every second cycle according to the calculated positional value.

In addition, the generating of the control signal may include taking a proportional and integral action on the difference between the position-controlled value and the calculated positional value of the motor; calculating a torque-controlled value based on subtraction of a value obtained by multiplying the rotational speed by a first constant and a value obtained by multiplying the positional value by a second constant, from a value obtained through the proportional and integral action; and generating a torque-controlled signal according to the calculated torque-controlled value.

In addition, the generating of the torque-controlled signal may receive and calculate the speed of the motor measured from a motor speed measuring device every second cycle.

3

In addition, the generating of the torque-controlled signal may generate a current-controlled value according to the torque-controlled value, perform vector control based on the generated current-controlled value and the current sensing value of the motor to generate a voltage-controlled value, and generate the torque-controlled signal based on the generated voltage-controlled value.

In another embodiment, an elevator controlling device includes a position storage unit that stores the positional value of an elevator driving motor; a control signal processing unit that receives the positional value of the motor from the position storage unit every first cycle, calculates the speed of the motor every second cycle, and generates a control signal for controlling the motor every third cycle; and a motor driving unit that controls the driving of the motor based on the control signal.

In addition, the elevator may include a motor; a motor position measuring unit that calculates and transmits the positional value of the motor to the elevator controlling device; a position storage unit that stores the positional value of the motor; a state feedback position controlling unit that receives the positional value of the motor from the position storage unit every first cycle, receives the speed of the motor, and outputs a torque-controlled value to control the motor; a state estimating unit that estimates the speed of the motor based on the torque-controlled value and the positional value every second cycle and transmits the result to the state feedback position controlling unit; a vector controlling unit that generates a current-controlled value based on the torque-controlled value and outputs a voltage-controlled value according to the current-controlled value and the driving current of the motor; and a motor driving unit that controls the driving power source of the motor according to the voltage-controlled value.

In addition, the state feedback position controlling unit may take a proportional and integral action on the difference between the position-controlled value and calculated positional value of the motor and may output, as a torque-controlled value, subtraction of a value obtained by multiplying the rotational speed by a first constant and a value obtained by multiplying the positional value by a second constant, from a value obtained through the proportional and integral action.

In addition, the control signal processing unit may include a state feedback position controlling unit that outputs the torque-controlled value of the motor according to the calculated positional value and the rotational speed of the motor, and the control signal processing unit may output a control signal to the torque of the motor based on the torque-controlled value.

In addition, the state feedback position controlling unit may take a proportional and integral action on the difference between the position-controlled value and calculated positional value of the motor and may output, as a torque-controlled value, subtraction of a value obtained by multiplying the rotational speed by a first constant and a value obtained by multiplying the positional value by a second constant, from a value obtained through the proportional and integral action.

In addition, the elevator controlling device may include a current sensor that senses the driving current of the motor; and a vector controlling unit that outputs a voltage-controlled signal based on the current-controlled value and driving current of the motor received from the current sensor, and the state feedback position controlling unit may generate and transmit a current-controlled value according to the torque-controlled value to the vector controlling unit.

In addition, the control signal processing unit may include a speed estimating unit that estimates the rotational speed of

4

the motor according to the control signal and calculated positional value every second cycle.

In addition, the control signal processing unit may acquire the speed of the motor measured from a motor speed measuring device.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a diagram describing an example of a speed controlling device according to the related art to decrease load compensation.

FIG. 2 is a diagram schematically illustrating the overall elevator system including the speed controlling device of an elevator according to an embodiment.

FIG. 3 is a diagram illustrating a configuration of a control signal processing unit 110 of an elevator controlling device 100 according to an embodiment.

FIG. 4 is a control diagram conceptually illustrating a configuration of a state feedback position controlling unit 111 according to an embodiment.

FIG. 5 is a control diagram illustrating an operation of a state estimating unit 113 of an elevator controlling device 100 according to an embodiment.

FIG. 6 is a diagram describing an experiment made using a sample motor including an elevator controlling device 100 according to an embodiment.

FIG. 7 is a graph illustrating a result of emulating and controlling an elevator using such a sample motor.

FIG. 8 is a flow chart illustrating a speed controlling method of an elevator according to an embodiment.

DETAILED DESCRIPTION OF THE EMBODIMENTS

The terms or words used in the specification and claims should not be narrowly construed as typical or denotative meanings. Rather, they should be construed as meanings or concepts matching the technical spirit of an embodiment based on the principle that inventors may properly define the concepts of the terms to describe their inventions in the best way.

Thus, since embodiments described in the specification and configurations illustrated in figures are just most preferable examples and do not fully represent the technical spirit of embodiments, it should be understood that there may be various equivalents and variations that replace embodiments at the time of filing this application.

FIG. 2 is a diagram schematically illustrating a power transforming device according to an embodiment.

Referring to FIG. 2, an elevator system including a speed controlling device 100 according to an embodiment includes an elevator driving motor 200, a control device 100 for controlling the motor 200, an encoder 210 for measuring the rotational state of the motor, and a motor position measuring device 200 for measuring a motor position (an rotational angle) from the pulse output of the encoder 210.

The control device 100 includes a control signal processing unit 110, a PWM gating signal generating unit 120, and a PWM inverter unit 130.

The control signal processing unit 110 may generate a control signal for decreasing the rollback phenomenon of an elevator without a load-cell. The control signal processing unit 110 performs signal processing for controlling the motor using state feedback position control as will be described below and using state estimating.

5

The PWM gating signal generating unit **120** may input a driving signal to the motor according to the signal processed in the control signal processing unit **110**.

The PWM inverter unit **130** may be switched according to the driving signal that has been generated from the PWM gating signal generating unit **120**.

These PWM gating signal generating unit **120** and PWM inverter unit **130** may serve as a motoring driving unit that controls the driving of the motor according to a voltage-controlled signal.

Meanwhile, the encoder **210** may be connected to the motor **200**, output pulses according to the rotation of the motor **200**, and transmit them to the motor position measuring device **220**.

The motor position measuring device **220** measures a motor position value or rotational angle θ , and transmits it to the control signal processing unit **110**. At this point, the motor position measuring device **220** calculates the positional value of the motor, rotational angle based on the pulse signals received from the encoder **210**. The motor position measuring device **220** may use an M/T scheme, for example. The M/T scheme is a scheme that uses a certain time and a pulse signal measured from the encoder **210** according to the driving of the motor **200**. The M/T scheme enables the rotational speed and rotational angle of the motor **200** to be measured as digital values. Thus, the motor position measuring device **220** may measure the current position (rotational angle) by counting pulses for a certain time. In addition, such a motor position measuring scheme may include methods that measure the number of pulses or the interval between pulses. It should be noted that the M/T scheme capable of being used in the embodiment is a scheme that supplements drawbacks of the schemes of measuring the number of pulses and the interval of pulses by combining them.

Meanwhile, the current sensor **230** senses current values currently flowing in the motor **200** for the current vector control of the control signal processing unit **110** as will be described below, and transmits them to the control signal processing unit **110**.

FIG. 3 is an exemplary diagram illustrating more in detail a configuration of the control signal processing unit **110** of an elevator controlling device **100** according to an embodiment.

Referring to FIG. 3, the control signal processing unit **110** of the elevator controlling device **100** may include a state feedback position controlling unit **111** that generates a control signal for controlling the torque of a motor according to the current position of the motor and the estimated motor speed, a position storage unit **112** that stores the current position of the motor and updates the motor position on a certain cycle, a state estimating unit **113** that estimates the speed of the motor according to the stored motor position and a torque-controlled value received from the state feedback position controlling unit **111**, and a vector controlling unit **114** that receives the current and current-controlled value sensed and outputs a voltage-controlled signal.

The state feedback position controlling unit **111** receives the positional value of the motor from the motor position measuring device **220**, receives the estimated speed of the motor from the state estimating unit **113**, and outputs the controlled current value of the motor for decreasing the rollback phenomenon of an elevator.

The state estimating unit **113** estimates the speed of the motor based on the positional value of the motor stored in the position storage unit **112** and the torque-controlled value received from the state feedback position controlling unit **111**.

6

The vector controlling unit **114** receives the current driving current measurement of the motor from the current sensor **230**, eventually controls an elevator motor voltage based on the driving current measurement and the controlled current value received from the state feedback position controlling unit **111**, and outputs a voltage-controlled signal as a signal for decreasing a rollback phenomenon.

The vector controlling unit **114** may operate in response to an interruption of a first cycle. In addition, the state estimating unit **113** may regularly operate in response to an interruption of a second cycle. The state feedback position controlling unit **111** may operate in response to an interruption of a third cycle. At this point, the state estimating unit **113** must perform quick calculation on the change in position. Thus, the interruption cycle of the state estimating unit **113** may be designed to be shorter than those of the other interruptions. The state feedback position controlling unit **111** may be designed to be performed at 1 ms interruption to be not frequently performed. However, since a relative effect in case of designing each cycle may be different, the embodiment may differently set the cycles of interruptions according to a method of designing the inverter of an elevator.

In addition, the second cycle may be set to be the same to the first cycle and it is possible that a design is made to be able to include the cycles one another.

FIG. 4 is a control diagram illustrating a configuration of the state feedback position controlling unit **111** according to an embodiment.

Referring to FIG. 4, the state feedback position controlling unit according to an embodiment is described.

The state feedback position controlling unit **111** may be configured as illustrated in FIG. 4. Input θ^* represents a position to be controlled. For example, a positional value to be controlled at a general elevator becomes zero to decrease a rollback phenomenon. In other words, a user may set the final position of the motor to be controlled according to the embodiment.

In addition, the state feedback position controlling unit **111** may calculate the difference between the position-controlled value θ^* input in this way and the current positional value θ of the motor and take a proportional and integral action according to a proportional constant $K1$. If a value obtained by multiplying the speed ω of the motor by $K2$ and a value obtained by multiplying the current position θ of the motor by $K3$ is subtracted from the value obtained from the proportional and integral action according to $K1$, a torque-controlled value T^* for control is generated. At this point, the state feedback position controlling unit **111** may generate a current-controlled value based on the value T^* generated and transmit the result to the vector controlling unit **114**.

At this point, the speed ω of the motor may be calculated through an integral action based on the current load TL and the torque-controlled value T^* as in the reference numeral **400** in FIG. 4. Alternatively, a speed value observed from another device may also be input. Thus, ω may be a value that is input from the outside. In addition, ω may be a speed estimating value that has been output from the state estimating unit **113**.

In addition, although the current positional value θ of the motor may be calculated through an integral action on a speed value, it may be calculated with a positional value measured from the encoder **210** and the motor position measuring device **220** as described above.

Meanwhile, if such a state feedback position controlling unit **111** is configured, a transfer function for the motor position (rotational angle) may be acquired as the following Equation 2.

$$\theta = \frac{K_1}{Js^3 + K_2s^2 + K_3s + K_1} \theta^* - \frac{s}{Js^3 + K_2s^2 + K_3s + K_1} T_l \quad (\text{Equation 2})$$

At this point, if the gain of the state feedback position controlling unit **111** is α , the gain equation of triple root may be $K_1 = -J\alpha^3$, $K_2 = -3J\alpha$, and $K_3 = 3J\alpha^2$. J represents an inertia value, and S means a Laplace operator. The inertia value is determined by factors, such as an elevator car, passengers, and a rope. The gain α is a polar value and preferably has a negative value. In addition, a range capable of being set for each coefficient may vary depending on the configuration of a system.

As in Equation 2, if designing a transfer function on a load torque in the same configuration as in FIG. 4, K_1 , K_2 , and K_3 may be freely designed. Thus, although a design is made to have triple root, a problem does not occur.

FIG. 5 is a control diagram illustrating the operation of the state estimating unit **113** of an elevator controlling device **100** according to an embodiment.

Referring to FIG. 5, the state estimating unit **113** receives a torque-controlled value T^* and a motor position value θ as inputs, and outputs a speed estimating value ω based on this.

As such, the state estimating unit **113** may estimate the speed of the motor according to the torque-controlled value and the motor position value. This enables faster processing than a process of actually measuring and calculating speed to enable effective control on an elevator.

Meanwhile, in the control diagram of FIG. 5, it is possible that $11 = -3\beta$, $12 = 3\beta^2$, $13 = \beta^3 J$. The value β is the gain of the state estimating unit **113**, and J means an inertia value that is determined by factors, such as an elevator, passengers, and a rope. In order to obtain more effective result, the gain β of the state estimating unit **113** preferably uses a greater value than the gain α of the state feedback position controlling unit.

FIG. 6 is a diagram describing an experiment made using a sample motor including an elevator controlling device **100** according to an embodiment.

Looking into the configuration diagram of FIG. 6, the encoder of the sample motor may be a 2000 pulse sin/cos encoder. The encoder of the sample motor may output 2000 sin/cos signals per rotation.

The sin/cos signal is input to an inverter **1**. The signal may be converted into 32768 A/B pulses using an RD converter used in a resolver. The pulsed converted may be applied to the position control. The overall inertia of a system is 0.084 kgms. In addition, the sample motor includes a brake and may be used for emulating the brake of an elevator.

Meanwhile, parameters for the sample motor are represented in the following Table 1.

TABLE 1

Items	parameters
Rated Voltage	220 V
Rated Current	20.2 A
Ld	1.11 mH
Rs	0.059 Ohm
Pole	8

FIG. 7 is a graph illustrating a result of emulating and controlling an elevator using such a sample motor.

Referring to FIG. 7, the position control deviation of an elevator controlling device **100** may be recognized, which uses a state feedback position controlling unit **111** according to an embodiment.

It may be checked that the elevator controlling device **100** according to the embodiment may control an amount of roll-back within 0.5 degree as illustrated in FIG. 7.

In addition, in this experiment, the state estimating unit **113** has been used as the speed feedback value of the state feedback position controlling unit **111**. As a result, a control bandwidth may further increase using the state estimating unit **113**. Meanwhile, the state feedback position controlling unit **111** has operated on an interruption cycle of 1 ms, and the state estimating unit **113** has been performed on a shorter PWM interruption cycle of 125 us.

FIG. 8 is a flow chart illustrating a speed controlling method of an elevator according to an embodiment.

Referring to FIG. 8, a motor position value is calculated from the encoder **210** connected to the motor **200**, in step **S100**.

The state estimating unit **113** estimates the speed of the motor through processes described above, in step **S110**.

The state feedback position controlling unit **111** generates a torque-controlled value based on the estimated motor speed and the motor position value, in step **S120**.

The state feedback position controlling unit **111** generates a current-controlled signal according to the torque-controlled value, in step **S130**. The vector controlling unit **114** receives a motor current sensing value and generates a voltage-controlled signal according to the current-controlled signal, in step **S140**.

The motor driving units **120** and **130** including e.g. a PWM signal generator input a PWM signal to the motor **200** according to the voltage-controlled signal to input a driving power source, in step **S150**.

The motor **200** may perform torque control according to a driving power source, in step **S160**.

Although the invention has been described above based on exemplary embodiments, these are just examples and do not define the invention, and those skilled in the art may appreciate that various variations and applications not illustrated above may make within the scope falling within the essential feature of the invention. For example, each component particularly illustrated in embodiments may be varied. In addition, differences related to such variations and applications should be construed to be included in the scope of the invention that is defined in the accompanying claims.

What is claimed is:

1. An elevator controlling method, comprising:

calculating the positional value of an elevator driving motor the every first cycle;
generating a control signal every third cycle to control the motor based on the calculated positional value and the rotational speed of the motor calculated every second cycle; and

controlling the driving power source of the motor based on the generated control signal,

wherein the generating of the control signal comprises:

taking a proportional and integral action on the difference between the position-controlled value and the calculated positional value of the motor;

calculating a torque-controlled value based on subtraction of a value obtained by multiplying the rotational speed by a first constant and a value obtained by multiplying the positional value by a second constant, from a value obtained through the proportional and integral action; and

generating a torque-controlled signal according to the calculated torque-controlled value.

2. The method according to claim 1, wherein the generating of the control signal further comprises estimating the rota-

9

tional speed of the motor by the control signal every second cycle according to the calculated positional value.

3. The method according to claim 1, wherein the generating of the torque-controlled signal receives and calculates the speed of the motor measured from a motor speed measuring device every second cycle. 5

4. The method according to claim 1, wherein the generating of the torque-controlled signal generates a current-controlled value according to the torque-controlled value, performs vector control based on the generated current-controlled value and the current sensing value of the motor to generate a voltage-controlled value, and generates the torque-controlled signal based on the generated voltage-controlled value. 10

5. An elevator controlling device, comprising:

a control signal processing unit that receives a positional value of the motor every first cycle, calculates the speed of the motor every second cycle, and generates a control signal for controlling the motor every third cycle; and a motor driving unit that controls the driving of the motor based on the control signal, 15 20

wherein the control signal processing unit includes a state feedback position controlling unit that outputs the torque-controlled value of the motor according to the calculated positional value and the rotational speed of the motor, and wherein the control signal processing unit outputs a control signal to the torque of the motor based on the torque-controlled value, and 25

wherein the state feedback position controlling unit takes a proportional and integral action on the difference between the position-controlled value and calculated positional value of the motor and outputs, as a torque-controlled value, subtraction of a value obtained by multiplying the rotational speed by a first constant and a value obtained by multiplying the positional value by a second constant, from a value obtained through the proportional and integral action. 30 35

6. The device according to claim 5, further comprising: a motor;

10

a motor position measuring unit that calculates and transmits the positional value of the motor to the elevator controlling device;

a state feedback position controlling unit that receives the positional value of the motor every first cycle, receives the speed of the motor, and outputs a torque-controlled value to control the motor;

a state estimating unit that estimates the speed of the motor based on the torque-controlled value and the positional value every second cycle and transmits the result to the state feedback position controlling unit;

a vector controlling unit that generates a current-controlled value based on the torque-controlled value and outputs a voltage-controlled value according to the current-controlled value and the driving current of the motor; and a motor driving unit that controls the driving power source of the motor according to the voltage-controlled value.

7. The device according to claim 5, further comprising: a current sensor that senses the driving current of the motor; and

a vector controlling unit that outputs a voltage-controlled signal based on the current-controlled value and driving current of the motor received from the current sensor, and

wherein the state feedback position controlling unit generates and transmits a current-controlled value according to the torque-controlled value to the vector controlling unit.

8. The device according to claim 5, wherein the control signal processing unit includes a speed estimating unit that estimates the rotational speed of the motor according to the control signal and calculated positional value every second cycle.

9. The device according to claim 5, wherein the control signal processing unit acquires the speed of the motor measured from a motor speed measuring device.
